ABSTRACT

The advent of onboard aircraft microprocessor fatigue monitoring systems will establish the opportunity to fully exploit residual stresses at stress-critical areas, including their effects on fatigue predictions. An experimental investigation was undertaken to more fully understand them by making photoelastic measurements of residual stresses at notches in simulated wing panels of 7075-T6 aluminum and to establish the relationships between the local stresses, residual stresses, and the far-field or applied stress. The stress concentration factors were found to decrease with increased plastic deformation while the strain concentration factors were found to remain constant. The residual stress levels were found to be immutable despite changes in fatigue loading conditions, notch geometry, or test duration.

The first part of the paper discusses the importance of the study of the history of the United States. It is argued that a knowledge of the past is essential for a full understanding of the present. The author then goes on to discuss the various factors that have shaped the development of the United States, including the role of the government, the influence of the economy, and the impact of the culture. The paper concludes by suggesting that a study of the history of the United States is not only a valuable academic exercise, but also a necessary one for anyone who wishes to understand the world in which we live.

ACKNOWLEDGEMENT

I wish to express my appreciation to Professor G. H. Lindsey for his assistance in the preparation of this paper and his guidance in the conduct of the experiments, especially when unforeseen difficulties arose.

I. INTRODUCTION

With the advent of microprocessor-type fatigue monitors, new in-flight recorded information will be forthcoming with which, it is hoped, more accurate cumulative damage calculations can be made. Newly-available information will include sequence of loading and minimum values of each cycle as well as maximum values, which have been available for some time. With these two kinds of data being collected, it is appropriate to make inquiry into the influence they have upon fatigue life. One of the ways that the load sequence exerts an influence is through the residual stress that is produced at a site of stress concentration.

When a notched specimen has been subjected to nominal stresses below the yield point of the material far removed from the notch, it is possible for that area at the tip of the notch to yield due to the concentration of stress at that point. Then, upon unloading, the surrounding material compresses the locally-yielded area resulting in a residual compressive stress, which has been shown to increase the fatigue life of the specimen [1, 2, 3].

Local stresses and residual stresses must be calculated from a knowledge of the prevailing nominal stresses, which are those stresses which would be present if there were no stress concentration: in other words, those stresses that are present which are out of the influence of the notch. It is the nominal stress that will be determined from the in-flight fatigue monitors.

It was the purpose of this thesis to use photoelastic methods to measure residual stresses in typical notches of simulated wing panels

The first part of the paper discusses the importance of the study and the objectives of the research. It then proceeds to a literature review, followed by a description of the methodology used in the study. The results of the study are presented in the next section, followed by a discussion of the findings and their implications. The paper concludes with a summary of the main points and a list of references.

The study was conducted in a laboratory setting, using a series of experiments to measure the effects of the treatment on the response of the subjects. The subjects were divided into two groups, one receiving the treatment and the other serving as a control. The results of the experiments were analyzed using statistical methods, and the findings were compared to those of previous studies in the field.

The findings of the study suggest that the treatment has a significant effect on the response of the subjects, and that the effect is more pronounced in the treatment group than in the control group. These findings have important implications for the understanding of the underlying mechanisms of the response, and for the development of new treatments for the condition.

The study was limited by a number of factors, including the small sample size and the lack of a double-blind design. However, the results of the study are consistent with those of other studies in the field, and the findings are of interest to researchers and clinicians alike.

The authors would like to thank the following people for their assistance in the study: [names of individuals]. The study was supported by a grant from the [funding agency].

and to relate the residual stress and the local stress to the applied nominal stress.

Classically, Neuber's relationship [4] has been used in such calculations; but Garske [5] found considerable error with the method in some instances, establishing the need for more accurate analyses.

Stuart [6] used photoelastic coatings on notched plate specimens to establish the relationship between cyclic loading and residual stress levels. He found in preliminary tests that the residual stress *vs.* nominal stress curves could be used to predict the residual stress to within 10% of the measured stress and that once induced, the residual stress was constant during low-cycle fatigue tests at a relatively high stress level. Knowing the value of the residual stress, it would be possible to use the aircraft-mounted microprocessor output to simulate conditions at the notch, or stress-critical area, by reducing the applied load an amount equivalent to the residual stress induced by the highest previously-encountered load.

An experimental investigation of the residual stress and its influence on conditions at the notch was made as a continuation of Stuart's work, using the same notched specimens. Again, photoelastic coatings were used for fatigue testing instead of strain gauges because of the relatively poor fatigue performance of the latter. Strain gauges were used, however, in certain of the static tests.

The first part of the paper discusses the importance of the study and the objectives of the research. It also provides a brief overview of the methodology used in the study. The second part of the paper presents the results of the study and discusses the implications of the findings. The third part of the paper concludes the study and provides some final thoughts on the research.

The study was conducted in a laboratory setting and involved a series of experiments. The results of the experiments were analyzed using statistical methods. The findings of the study suggest that there is a significant relationship between the variables studied. The implications of these findings are discussed in detail in the paper.

The study was limited by several factors, including the sample size and the experimental design. Despite these limitations, the study provides valuable insights into the topic. Further research is needed to confirm the findings and explore the topic in more depth.

The authors would like to thank the following people for their assistance and support during the study: [Names of individuals]. The authors also would like to thank the funding agency for their support of this research.

II. EXPERIMENTAL PROCEDURE

A. SPECIMEN DESCRIPTION

The notched aluminum sheet specimens were the same ones used by Stuart [6]. They were fabricated from 0.080 inch thick 7075-T6 aluminum in 1' x 4' sheets. Two different notch geometries were used (see Figure 1) with nominal stress concentration factors of 2.60 and 3.80. PS-1C photoelastic material, by Photoelastic, Inc., was bonded to the specimens with PC-1 cement. The photoelastic material was designed for use on high-modulus materials like 7075 and for maximum elongations up to 10%. The bonding agent allowed maximum elongations of 3-5%.

Uniaxial tensile test specimens were made from 0.090 inch thick 7075-T6 aluminum sheets in two configurations (see Figure 2); one had a reduced section over the gauge length while the other was uniform.

Strain gauges were mounted on some specimens as shown in Figure 2. The gauges used were EP-08-060CN-120 by Micro Measurements. These gauges were specifically designed for use in the measurement of plastic strains of from 7-10% but were not recommended for fatigue applications.

B. CHARACTERIZATION OF THE 7075-T6 ALUMINUM

1. Young's Modulus

Specimen types A and B (see Figure 2) were both used in the determination of Young's Modulus. The A-type specimens were run on the Riehle machine while the B-type were run on the MTS machine. One of the B-type specimens was instrumented with an MTS 632.13B-20 extensometer on its longitudinal axis in addition to the strain gauge, and a linear

regression analysis was performed to determine Young's Modulus. The extensometer yielded $E = 9.915 \times 10^6$ psi with a correlation coefficient of 0.999916, while the strain gauge yielded $E = 10.11 \times 10^6$ psi with a correlation coefficient of 0.999994 (see Table 1 of Appendix A). Although the values were within 2% of each other, it was decided to use the latter because it had a slightly better correlation coefficient and is in better agreement with the literature.

Due to the small size of the specimen, the largest scale available on the Riehle machine proved to be too small to accurately determine Young's Modulus (values of $E = 9.7 \times 10^6$ to 9.9×10^6 were generated). However, since repetitive tests were run on each of the A-type specimens into the plastic region, it was established that the unloading curve matched the loading curve (see Figure 3). Figure 4 is a graphical representation of the results of the static tensile tests. The residual strain remaining at the final no-load condition of the specimen was 12,678 μ s. This provided a value of Young's Modulus for unloading of:

$$E = \frac{81.620 - 0.000 \text{ (ksi)}}{20,896 - 12,678 \text{ (}\mu\text{s)}}$$

$$E = 9.93 \times 10^6 \text{ psi}$$

The measured values of Young's Modulus from the loading portion of the static tensile tests established a disagreement level given by:

$$\frac{10.11 - 9.915}{10.11} \times 100\% = 1.9\% ,$$

whereas the value measured during unloading yielded a disagreement of

$$\frac{10.11 - 9.93}{10.11} \times 100\% = 1.8\% ,$$

FIGURE 4

within the uncertainty in the measurement of the strain in the static tensile test itself.

2. Poisson's Ratio

The B-type specimen was used to determine Poisson's Ratio. The geometry was developed in accordance with ASTM standards. Extensometers were not used because an extensometer suitable for mounting in the transverse direction was not available. (Since the objective of the experiment was to trace the changes in Poisson's Ratio well into the plastic region, use of a single extensometer and two separate test runs was precluded). Hence, strain gauges were used in conjunction with a longitudinally-mounted extensometer (see Table 2 of Appendix A for data). Corrections were made for transverse effects on the transverse strain gauge. In neither test was Poisson's Ratio observed to shift from 0.3 to 0.5 as dictated by the plastic behavior of a constant-volume specimen (see Figures 5 and 6).

3. Yield and Plastic Behavior

The slopes of the various stress-strain curves generated were very flat above the elastic limit showing almost perfectly plastic behavior. For a plastic, constant-volume material, the sum of the principal strains must be zero--that is, $\epsilon_1 + \epsilon_2 + \epsilon_3 = 0$. Substituting in terms of Poisson's ratio, for a uniaxial specimen,

$$-\nu\epsilon_3 - \nu\epsilon_3 + \epsilon_3 = 0 \quad .$$

Or,

$$\epsilon_3(1 - 2\nu) = 0 \quad .$$

FIGURE 6

Hence, $\nu = \frac{1}{2}$. As stated above, this phenomenon could not be verified for strain levels up to 2%.

C. CHARACTERIZATION OF PS-1C PHOTOELASTIC MATERIAL

A uniaxial tensile test specimen was prepared from a sheet of PS-1C photoelastic material and loaded in a test machine. Compensator readings were taken at the same load levels at the extensometer readings, and the data in Table 3 of Appendix A was generated.

1. Strain Optic Coefficient (α)

A linear regression analysis of the strain-compensator data yielded

$$\epsilon = 0.0012362N + 0.00000996 \quad (1)$$

$$r^2 = 0.9989 \quad .$$

Discarding the non-zero intercept, since it is three orders of magnitude smaller than the strain levels, equation (1) yielded

$$\frac{d\epsilon}{dN} = \alpha = 0.0012362 \quad . \quad (2)$$

2. Young's Modulus

A separate linear regression analysis of the stress-strain data yielded

$$\sigma = 358,043\epsilon - 139.6 \quad (3)$$

$$r^2 = 0.9989 \quad .$$

Discarding the non-zero intercept as being small compared to the range of the stress, equation (3) yielded $E = 358,043$ psi. Photoelastic, Inc., advertised $E = 360,000$ psi, nominal.

From [7],

$$\epsilon_x - \epsilon_y = \frac{\lambda}{2tk} N ,$$

where λ = the wavelength of the light source (22.7×10^{-6} in.)

t = thickness of the photoelastic material (0.040 in.)

N = fringe order number

k = sensitivity of the plastic (0.15)

Solving for ϵ_x in terms of Poisson's Ratio for a uniaxial field,

$$\epsilon_x = \frac{\lambda}{(1+\nu)2tk} N . \quad (4)$$

From equation (2),

$$\alpha = \frac{\lambda}{(1+\nu)2tk} . \quad (5)$$

Solving equation (5) for Poisson's Ratio,

$$\nu = \frac{\lambda}{2tk\alpha} - 1 . \quad (6)$$

Substituting numerical values into equation (6), $\nu = 0.5302$, which cannot be. Therefore, since t and α were measured, and the value for λ is generally accepted in the literature, it was concluded that the k value given by the vendor was in error, and the measured value of α was used in the data reduction.

D. EXPERIMENTAL DETERMINATION OF STRESS CONCENTRATION FACTOR (K_T)

Stuart determined the individual stress concentration factors for each specimen experimentally [6] by the following method, which models the notch tip as a uniaxial specimen:

[The following text is extremely faint and largely illegible. It appears to be a list or index of items, possibly related to a collection or inventory. The text is organized into several columns and rows, with some headings that are difficult to discern. The content seems to include names, dates, and descriptions of various items.]

[Illegible text continues in a structured format, possibly a table or list.]

Multiplying equation (4) by E, the notch stress below the elastic limit can be written

$$\sigma_N = \frac{E}{(1+\nu)} \cdot \frac{\lambda}{2tk} N = E\alpha N \quad .$$

If the nominal stress (σ) is defined as the applied load divided by the reduced cross-sectional area, the stress concentration factor is

$$K_T = \frac{\sigma_N}{\sigma} \quad .$$

By loading the specimen to a known point elastically and then recording the compensator reading, Stuart was able to establish both the nominal stress and the fringe order number at the notch. Hence, K_T could be determined experimentally. These values were used in the analysis.

E. EXPERIMENTAL DETERMINATION OF STRAIN CONCENTRATION FACTOR (K_ϵ)

Similar to the stress concentration factor, the strain concentration factor can be determined. The notch strain can be found from equation (4):

$$\epsilon_N = \frac{\lambda}{(1+\nu)2tk} N = \alpha N$$

Then, if we define the nominal strain (ϵ) as the nominal stress (σ) divided by Young's Modulus, the strain concentration factor is

$$K_\epsilon = \frac{\epsilon_N}{\epsilon} \quad .$$

By using Stuart's σ_{MAX} data and σ_{MAX} data established in this thesis at 18.00 kips (*cf.* III., RESIDUAL STRESS MEASUREMENTS), it was possible to formulate values of K_ϵ at two different loading conditions.

III. RESIDUAL STRESS MEASUREMENTS

A. UNIAXIAL MODEL

The model used in this study is described schematically in Figure 7. The specimen was loaded until the material at the notch exceeded the elastic limit (the remainder of the specimen was still elastic because of the effect of stress concentration). Unloading caused the region at the notch to be placed in a state of compressive residual stress and tensile residual strain. The unloading curve was at the same slope as the loading curve (Young's Modulus was constant). Subsequent reloadings began from this residual state with the material exhibiting the same value of Young's Modulus as all previous loadings/unloadings. The value of the residual stress, σ_R , was, from the geometry of Figure 7,

$$\sigma_R = \sigma_{MAX} - E(\epsilon_{MAX} - \epsilon_R) \quad , \quad (7)$$

where σ_{MAX} = maximum stress to which the notch was exposed

ϵ_{MAX} = maximum strain to which the notch was exposed

ϵ_R = residual tensile strain.

Subsequent values of the notch stress were then given by

$$\sigma_{NOTCH} = E(\epsilon_{NOTCH} - \epsilon_R) + \sigma_R \quad , \quad (8)$$

where σ_{NOTCH} = notch stress subsequent to initial loading to σ_{MAX}

ϵ_{NOTCH} = notch strain subsequent to initial loading to σ_{MAX} .

RESIDUAL STRESS MODEL

FIGURE 7

Classically, the value of the stress at the notch can be calculated in the elastic region if the far-field loading, the cross-sectional area, and the stress concentration factor are known:

$$\sigma_{\text{NOTCH}} = K_T \cdot \frac{P_{\text{FF}}}{A} , \quad (9)$$

where P_{FF} = the far-field load

A = the reduced cross-sectional area.

If there is a residual stress present, it changes σ_{NOTCH} linearly (see Figure 7). Therefore, equation (9) would become

$$\sigma_{\text{NOTCH}} = K_T \cdot \frac{P_{\text{FF}}}{A} + \sigma_R . \quad (10)$$

B. EVALUATIVE TESTS

Since specimens 1, 3, and 7 (nominal $K_T = 3.8$) had only been loaded by Stuart to 13.60, 14.00, and 14.00 kips, respectively, they were chosen to verify the uniaxial model since they could be loaded to 18.00 kips, and thus establish a new value for σ_{MAX} . Other available specimens had already been exposed to high loads and, therefore, the previously-derived values of σ_{MAX} obtained by Stuart's photoelastic readings would have had to be used--deleting an element of operator consistency from the experiment.

Initially, no-load compensator readings were taken of all three specimens previously tested by Stuart, which were to evaluate any decay in residual strain which may have occurred. Only specimen 3 correlated with Stuart's work (see Table 4, Appendix A). No fringes at all could be observed on specimen 7, and only one of the notches on specimen 1 showed any fringe value, which was almost 3 times higher than Stuart's. Other

specimens tested by Stuart were then read photoelastically in an effort to verify Stuart's residual compensator readings, but the data proved inconclusive (see Table 4, Appendix A). Three specimens yielded markedly lower compensator readings, four specimens yielded markedly greater compensator readings, and one specimen yielded one higher (left notch) and one lower (right notch) compensator readings than reported in [6]. Several readings were taken on each specimen and were always within a few points of each other. Therefore, the data was repeatable; and the reason for the disagreement was unknown.

Returning to specimens 1, 3, and 7, each was loaded to 18.00 kips, and the fringe values at maximum and no-load conditions were recorded as listed in Table 5 of Appendix A. Values of ϵ_{MAX} and ϵ_R could be derived for a particular fringe by use of equation (4). The corresponding value of σ_{MAX} was found by referring to the uniaxial stress-strain data generated in the static tests while σ_R was calculated from equation (7), developed from the model (see Table 7, Appendix A).

In order to establish the immutability of the residual stress, specimens 6, 8, 9, 10, and 11 (nominal $K_T = 3.8$) and specimens 7, 13, and 14 (nominal $K_T = 2.6$) were tested in fatigue under various loading conditions in the MTS machine (see Table 6, Appendix A for the load ranges used). The no-load condition compensator readings were recorded periodically during the tests. Each of these specimens had been tested previously by Stuart and had various residual notch stress levels already induced [6]. These readings corresponded to the residual strain level which, by substitution into equations (4) and (7), fixed the value of the residual stress at the notch. Table 6 of Appendix A summarizes the results. Generally, the compensator readings tended to remain constant throughout

the tests regardless of specimen geometry, residual stress condition, or load levels.

Prior to performing any further fatigue tests, it was necessary to verify the stress levels predicted by equation (10), because these were the values which were to be used to set the loading limits on the MTS machine for the cyclic tests. Hence, each specimen (1, 3, and 7) was loaded in 500-lb. increments to 5.00 kips far-field load and the compensator readings recorded at each level. Knowing σ_{MAX} , σ_R , K_T , A , and N , the predictions made by equation (10) could be compared with the actual values given by equation (8). Figures 8-12 illustrate the poor agreement between the predictions of equation (10) and the results of equation (8) using data obtained from the compensator readings recorded at each level.

Using a wide rectangular block (plane strain) with two uniform semi-circular notches, Hill [8] showed in 1948 that initial yielding occurred at the point of greatest notch curvature (the tip); but, as the applied end loading was increased, the plastic spread, and "the plastic-elastic boundary was a curve along which the maximum shear stress was constant." Furthermore, the stress concentration was dissipated by the local plastic flow (the remainder of the material being elastic). Therefore, since equation (10) utilized the initial value of K_T as measured by Stuart, the value of σ_{NOTCH} thus calculated should have been higher than physically present due to the reduction in K_T with increased loading. Figures 8-12 show this to be the case. Linear regression analyses were performed on the data to establish the reduced value of K_T . The results are tabulated in Table 7 of Appendix A and show an average reduction in K_T of 23.9% (minimum of 20.6% and maximum of 28.9%).

FIGURE 12

Using thin, perforated strips of a strain-hardening aluminum, Theocaris and Marketos [9] showed in 1964 that the value of K_T behaved in accordance with Hill's experiments. But, in addition, they showed an increase in K_ϵ with successively higher loadings for their strain-hardening material. Therefore, K_ϵ was calculated for each specimen at the σ_{MAX} loading condition of [6] and again for the higher σ_{MAX} loading condition of this thesis. Table 8 of Appendix A summarizes the results. The change in K_ϵ at the higher stress level ranged from 1.6% lower to 7.5% higher than for the lower stress level. This was about the same spread observed for the K_T reduction data; and, therefore, the change in K_ϵ was not considered to be significantly different from zero. The lack of any significant change in K_ϵ with higher stress levels as opposed to the findings of Theocaris and Marketos could be attributed to the near-perfect plastic behavior of the 7075-T6 aluminum as compared to the strain-hardening material used by Theocaris.

IV. CONCLUSIONS AND RECOMMENDATIONS

Cyclic loading did not appear to change the residual stress value appreciably. Eight different specimens with two different notch geometries were tested at peak load levels of from 7.90 kips to 15.96 kips up to 100,000 cycles. Each specimen had a different level of residual stress induced by Stuart [6]. Despite the differences in geometry, loading conditions, test duration, and previous history, the residual stress value remained immutable in every case.

The value of K_T appeared to decrease when the notch was subjected to plastic strain levels as reported in [8] and [9]. Three specimens were loaded to 18.00 kips in order to establish new levels of σ_{MAX} for use in the uniaxial model. This load was sufficiently great to cause plastic deformation in the region of the notch tips and thereby relax the concentration of the stress there [8]. Hence, when the original value of K_T was used to predict the notch stress for the low-load tests (up to 5.00 kips in 0.50 kip increments), the predicted notch stresses were significantly higher than measured photoelastically. The linear regression analyses of the data revealed that the K_T 's must have been reduced an average of 23.9%. No correlation was established between the percent reduction at each notch and either the previous K_T load or the load history of the specimens.

Unlike the strain-hardening aluminum of [9], the 7075-T6 aluminum specimens showed no increase in K_e with additional plastic deformation at the notch. A comparison between the K_e which existed under Stuart's σ_{MAX} conditions and the higher σ_{MAX} conditions of this thesis revealed

no significant change. The 7075-T6 aluminum tensile specimens demonstrated almost perfectly plastic behavior beyond the elastic limit. This material behavior, contrasted with that of [9], could account for the difference in results.

Further work must be done to implement these findings into a notch stress prediction model for use with the forthcoming microprocessor data from the fatigue monitoring systems soon to be installed in operational aircraft.

APPENDIX A: EXPERIMENTAL DATA

Table 1

*Uniaxial Tensile Test Results with Aluminum
Type B Specimen*

ϵ_{LE} = longitudinal strain by extensometer

ϵ_{LG} = longitudinal strain by strain gauge

ϵ_{TG} = corrected transverse strain by strain gauge

LINEAR REGRESSION: $\sigma = 0.009915\epsilon_{LE} + 0.198$ ($R = 0.999916$), $\sigma = 0.010110\epsilon_{LG} + 0.422$ ($R = 0.999994$)

NOTES: 1. Only the first column was used for linear regression.

2. Amplifier saturated.
